

Proportions-at-weight, a new Observation type

Matt Dunn, Ian Doonan, Teresa A'mar

March 2021

DRAFT

1. Overview

Overview

2. Conceptual Description

The observation `process_removals_by_weight` was added to allow the use of fish market data, where fish weights have been measured instead of fish lengths or ages, which are collated into proportions-at-weight. The observation is strictly from retained catch and is therefore associated with mortality from a defined fishery. When discarding is included in the model, the retained selectivity should be used for these data. If there is no discarding, then the total catch selectivity is used. However, for current coding purposes, this observation must be linked to a fishery as defined in a `mortality_instantaneous` block, which ignores discards and so the selectivity is that defined in the `mortality_instantaneous` block. We do not know of discard data being collected for fisheries that provide weight composition data (currently in 2021, just the bluenose fishery in New Zealand) and so this feature is being implemented in the `mortality_instantaneous` block only.

The expected proportions-at-weight are derived from normalizing the expected numbers-at-weight. There are two stages in calculating the expected numbers-at-weight. Firstly, CASAL2 calculates the expected numbers-at-length from the numbers-at-age using the age-length relationship specified in the `@age_length` block. Secondly, the numbers-at-length are converted into numbers-at-weight using the length-weight relationship specified in the `@length_weight` block and its distribution of weight about the mean weight-at-length. The length-weight distribution is currently applied in CASAL2 only in weight composition data and so the `cv` is specified in its `@observation` block.

The user must specify the units of weight for the proportions-at-weight observations (which may be g or kg), a vector containing the lower edge of each weight bin, a vector containing the proportions in each weight bin, and a vector containing the mean number of fish in a fishbox at that length bin, to adjust the CV of the length-weight distribution to account for the fact that these data are mean weights, not weights for a single fish as found in a length composition. Note that units for weight in the proportions-at-weight do not have to be the same as specified in `@length_weight`. Observation-specific weight bins must be in a strictly increasing sequence; there is no `@model/weight_bins` as in length composition observations. Observations may be specified for any category used in the partition, or for some combinations of them [LINK TO CATEGORY SECTION?], e.g., for both males and females separately, or alternately, one set for combined sex. The weight bins must be the same for each year; if this is not the case, then years for which they are different need to be entered as a different `process_removals_by_weight` block.

CASAL2 does not allow a weight plus group, so the data are specified in a vector of proportions-at-weight of length $n+1$, where n is the number of lower edges of each weight bin supplied (the final value provides the upper limit to the final bin). Note that a plus group can be mimicked by using a large terminal weight bin value.

CASAL2 generates a warning if the mean weight estimated for the youngest age in the partition is smaller than the lower size of the first weight bin. This is to guard against including weight observations that may have a substantial contribution from fish younger than the youngest age in the partition (`@model/min_age`).

The only likelihood currently available in CASAL2 for proportions_at_weight observations is the multinomial, with effective sample sizes for each year provided as `error_values`. Note that in the implementation of the multinomial likelihood in CASAL2, the weight bins having a value of zero will have no contribution to the likelihood.

No specification is made for the specific time within the time-step that the sample was taken. This is because the sample is linked to a fishery, where removals and observations are defined to be at the

mid-point of the fishing season.

Proportions-at-weight processes:

- `process_removals_by_weight_fishery` using `mortality_instantaneous`;
- `process_removals_by_weight_retained_fishery` using `mortality_instantaneous_retained`; Not coded in this release.
- `process_removals_by_weight_retained_total_fishery` using `mortality_instantaneous_retained`; Not coded in this release.

We have “general” observations like `process_proportions_at_length`, which are used for surveys, and can also be used for fisheries; they can be fitted at any time throughout the time-step. Weight frequencies are not collected on surveys, so we currently do not need this observation.

Length composition observation types for fisheries

Linked to `process_mortality_instantaneous`, CASAL2 has these fishery length composition data observations:

- `process_removals_by_length`: works with process of type `mortality_instantaneous`;
- `process_removals_by_length_retained`: works with process of type `mortality_instantaneous_retained`; and
- `process_removals_by_length_retained_total`: works with process of type `mortality_instantaneous_retained`

Weight data are currently collected in processing sheds and so discard data are not available. Discard data are not usually collected by observers on fishing vessels and so, again, there are generally no discard data. Hence, only the weight equivalent of `process_removals_by_length` is needed currently.

Fisheries process: `mortality_instantaneous`

Supply the time-step.

A specific fishery is a method in the `table method` sub-command in the `mortality_instantaneous` block. For one stock, it makes sense to have one `mortality_instantaneous` block that covers all fisheries on the stock (whatever time-step they occur in) and specifies the proportions of M that occurs in each time-step. Rather than covering one process in a specific time-step, `mortality_instantaneous` blocks cover the full year which makes it different from other processes. `mortality_instantaneous` blocks need to be like this so that M and F can occur simultaneously and to also make sure the various `U_max` parameters are evaluated at the same time if fisheries co-occur.

Proportions-at-weight observations

Copied from the manual, but changed into proportions-at-weight.

Proportions-at-weight observations can be supplied as

- a set of proportions for a single category (see example);
- a set of proportions for multiple categories; or

- a set of proportions across aggregated categories.

The method of evaluating expectations are the same for all three types of proportions.

Defining an observation for multiple categories extends the single category observation definition. It is used to model a set of proportions over several categories by weight bin. For example, to specify that the observations are of the proportions of male or females within each weight bin, then the sub-command categories is

```
categories male female
```

The vector of proportions will have the proportion for males over the specified weight bins, followed by the proportions for females. The sum over male and female proportions should be 1 (i.e., it implicitly has a sex ratio). [CASAL2 will issue a warning and normalize observation vectors that do not sum to 1. For length observations, the vector must sum to 1 otherwise an error is logged which seems to be unhelpful since generating these vectors may not sum to 1 if rounded, and requires a complete re-calculation if end parts are to be excluded.]

Defining an observation across aggregated categories allows categories to be aggregated before the proportions are calculated. To indicate that two (or more) categories are to be aggregated, separate them with a "+" symbol. For example, to specify that the observations are of the proportions of male and females combined within each weight bin, then the sub-command categories is

```
categories male + female
```

CASAL2 then requires that there will be a single vector of proportions supplied, with one proportion for each weight bin, and that these proportions sum to 1. CASAL2 will issue a warning and normalize observation vectors that do not sum to 1.

The latter form can then be extended to include multiple categories, or multiple aggregated categories, e.g., for an east and west combined sex proportions that incorporates an area ratio we could use

```
categories male.east + female.east male.west + female.west
```

CASAL2 then requires that there will be a vector made up by a concatenated of proportions for east and another for west, and that these proportions sum to 1. CASAL2 will issue a warning and normalize observation vectors that do not sum to 1.

3. Technical Description

3.1. Input sub-commands for weight frequency observation block

A weight composition data block has the structure:

```
@observation <label to be supplied>
type process_removals_by_weight
<other sub-commands>
:
```

The sub-commands that are available are shown in Table 3.1.

3.2. Numbers-at-age Expectation

The observation is supplied for a given year and time-step, for some selected age classes of the population (i.e., for a range of ages multiplied by a selectivity that is associated with the process).

Table 3.1: Input sub-commands for weight frequency observation block. “<X>” denote values or vectors that the user must supply (without the <>).

type process_removals_by_weight	Observation is for weight frequency data
method_of_removal <fishery label>	Fishery that this observation belongs to
time_step <time_step>	Not truly needed, but length code needs it currently
mortality_instantaneous_process <mortality block label>	Block that the fishery is defined in
length_weight_cv <CV>	CV for weight-at-length distribution
length_weight_dist <distribution label>	Weight-at-length distribution: either lognormal or normal
years <vector of years>	Specify years that have data.
categories <category specification>	Categories that the observation was collected from.
weight_unit <unit label>	Either g, kg, or t (tonnes)
delta <value>	Specify the robustification value for the likelihood; default 1e-11.
likelihood <likelihood label>	Distribution for the weight frequency. Only option currently is multinomial (N scales the variance.
length_bins <L long vector of lower bound for each length bin>	No plus-group allowed. These are indexed by 1 up to L
length_bin <cap for last bin>	CV for the weight-at-length distribution in the i^{th} length bin is $length_weight_cv / \sqrt{n_i}$.
length_bins_n <vector of n's, one for each length bin>	Optional. Weight of a fishbox, assumed to be constant, or nearly so for best results. If present, then CASAL2 will calculate length_bins_n for each category in the observation using $fishbox_weight / (a l^b)$
fishbox_weight <value>	No plus-groups allowed.
weight_bins <W long vector of the lower bound for each bin>	
weight_bin <cap for last bin>	
table obs ... end_table	Table sub-commands to enclose observations. Each row has the year followed by a vector of the fractions for each weight_bin. The data should sum to 1, but if not, CASAL2 will normalise it with a warning.
table error_values ... end_table	Table sub-commands to enclose the observation Ns. Each row has the year and the N for that year's observation.

The expectations from this observation are generated whilst the process is being executed. There is a chain of expectations starting with that for ages, then converting this into an expectation for lengths, and lastly, converting lengths into expectations over weight bins.

The expectation of numbers-at-age a for category c from exploitation method m ($E[N_{a,c,m}]$) are

$$E[N_{a,c,m}] = N_{a,c} U_{a,m} S_{a,c,m} 0.5 M_{a,c} \quad (3.1)$$

where $N_{a,c}$ are the numbers-at-age in category c before the process is executed, $U_{a,m}$ is the exploitation rate for age a from method m , $S_{a,c,m}$ is the selectivity, and M is the natural mortality. This works for age-based selectivity, but for length-based selectivity in an age-based model, a form of age-length transition is done, but the probabilities use numerical integration within an age bin, so there may be speed advantages to incorporating this into the age-length transition matrix calculations below. Given $U_{a,m}$ needs $S_{a,c,m}$, it is cleaner to keep length-based selectivity calculations separate for now.

3.3. Part 1: age-length transition

This observation uses its own specified length bins to make sure that the intermediate age-length transition is properly specified. This is in contrast to length compositions, which uses both an observation `length_bins` and a `@model/length_bin` specifications, i.e., specifications of weight composition data are independent of specifications for length data. Here, the length bins (lower bound) used are specified in the observation block with sub-command `length_bins`.

CASAL2 will check that the values are positive and strictly increasing.

The expected length distribution is calculated via a transition matrix, **Tal**, that converts an age into the vector of proportions by lengths bins; columns are ages, rows are length bin index so $Nl_{c,m} = \mathbf{Tal} N_{c,m}$, where Nl and N are (column) vectors indexed by category (c) and method (m), i.e., $Nl_{c,m,l} = \sum_{a=A_{min}}^{A_{max}} \mathbf{Tal}_{l,a,c} N_{c,m,a}$, where A_{min} and A_{max} are the specified minimum and maximum ages in `@model` block.

We drop the m subscript (method) from here on since it is clear which method is meant (i.e., data is from one fishery (=method in the `instantaneous_mortality` block)). Categories index (c) is still relevant.

For the normal distribution of length given an age, elements of **Tal** for length bin l and age a in category c are given by

$$\zeta_{l,a,c} = \left\{ \Phi \left(\frac{L_{l+1} - \bar{L}_{c,a}}{\sigma_{c,a}} \right) - \Phi \left(\frac{L_l - \bar{L}_{c,a}}{\sigma_{c,a}} \right) \right\} \quad \text{for } 1 \leq l < L \quad (3.2)$$

where Φ is the standard normal cumulative function with mean length $\bar{L}_{c,a}$ and standard deviation $\sigma_{c,a} = cv_{c,a} \bar{L}_{c,a}$; $cv_{c,a}$ is specified in the relevant `@age_length` block.

For the lognormal distribution, the L_l , $\bar{L}_{c,a}$ and $\sigma_{c,a}$ must be on the log scale, i.e.,

$$\zeta_{l,a,c} = \left\{ \Phi \left(\frac{\log L_{l+1} - (\log \bar{L}_{c,a} - \sigma_{c,a}^2/2)}{\sigma_{c,a}} \right) - \Phi \left(\frac{\log L_l - (\log \bar{L}_{c,a} - \sigma_{c,a}^2/2)}{\sigma_{c,a}} \right) \right\} \quad \text{for } 1 \leq l < L \quad (3.3)$$

where $\sigma_{c,a} = \sqrt{\log(cv_{c,a})^2 + 1}$, i.e., log scale standard deviation.

If growth is not time varying, then **Tal** should be calculated once. If length-weight relationships are time-varying, then **Tal** should be saved and re-used.

Recommendations

The age ranges specified in `@model` can exclude the youngest ages, but invariably it has a maximum age, usually with a plus-group. Both situations can create bias in predicting length distributions in certain circumstances. If the age plus-group is not located where the mean length is at L_∞ , some parts of the length distribution within the age plus-group are not represented and this will result in a bias for length composition data where a length plus-group is specified. This is only an issue in the early part of the model run when the fishdown is occurring, after which it will disappear as the age plus-group is emptied. A bias may also occur when the youngest ages are excluded if their length distribution(s) overlaps with the smaller length bins in the model. We recommend that the model starts at age 1 and finishes at a sufficiently old age that the mean length is almost at L_∞ .

As a check, CASAL2 will output the predicted mean length and the length at 3 x standard deviation above the mean for ages at `max_age`, `max_age + 5` and `max_age + 10` years. This will mean that growth functions can take ages outside the `@model` age range to predict mean length (it may do this already?).

3.4. Part 2: length-weight transition leading to age-weight transition

Here, **Tal** is converted into **TawO**, the age-weight transition matrix using the weight bins specified in the observation block, i.e., we do not have a `@model/weight_bins` sub-command that length data has. The specific weight bins are specified in the `@observation/weight_bins` sub-command. Weight bins must be positive and in strictly increasing order and CASAL2 will check that this is so.

An intermediate matrix is needed that converts length into a weight distribution, **Tlw**. This uses the specified length bins based on `@observation/length_bins` sub-command so it fits to the columns in **Tal**, i.e., $\mathbf{TawO} = \mathbf{Tal} \%*\% \mathbf{Tlw}$.

The numbers-at-weight-bin (column vector) is given by $NW_{c,w} = \sum_{l=L_{min}}^{L_{max}} \mathbf{Tlw}_{w,l,c} Nl_{c,l}$, where $L_{min} = 1$ and $L_{max} = (\text{terminal length} - 1)$.

From the section above, the numbers-at-length vector is $Nl_{c,l} = \sum_{a=A_{min}}^{A_{max}} \mathbf{Tal}_{l,a,c} N_{c,m,a}$. Substituting for $Nl_{c,l}$ and summing over the length bins

$NW_{c,w} = \sum_{l=L_{min}}^{L_{max}} \mathbf{Tlw}_{w,l,c} \sum_{a=A_{min}}^{A_{max}} \mathbf{Tal}_{l,a,c} N_{c,m,a}$ which rearranges to

$$NW_{c,w} = \sum_{a=A_{min}}^{A_{max}} \left(\sum_{l=L_{min}}^{L_{max}} \mathbf{Tlw}_{w,l,c} \mathbf{Tal}_{l,a,c} \right) N_{c,m,a}.$$

For the normal distribution of weight about length, elements of **Tlw** for weight bin w and length l in category c are given by

$$\zeta_{w,l,c} = \left\{ \Phi \left(\frac{W_{w+1} - \bar{W}_{c,l}}{\sigma_{c,l}} \right) - \Phi \left(\frac{W_w - \bar{W}_{c,l}}{\sigma_{c,l}} \right) \right\} \quad \text{for } 1 \leq w < W \quad (3.4)$$

where Φ is the standard normal cumulative function with mean weight $\bar{W}_{c,l}$ and standard deviation $\sigma_{c,l} = cv_{weight} \bar{W}_{c,l}$; cv_{weight} is specified as a constant for all lengths and categories in the `@observation/length_weight_cv` sub-command, but the l index is needed to account for more than one fish per fish box (see below). The lognormal version

$$\zeta_{w,l,c} = \left\{ \Phi \left(\frac{\log W_{w+1} - (\log \bar{W}_{c,l} - \sigma_{c,l}^2/2)}{\sigma_{c,l}} \right) - \Phi \left(\frac{\log W_w - (\log \bar{W}_{c,l} - \sigma_{c,l}^2/2)}{\sigma_{c,l}} \right) \right\} \quad \text{for } 1 \leq w < W \quad (3.5)$$

where $\sigma_{c,l} = \sqrt{\log(cv_{c,l})^2 + 1}$, i.e., log scale standard deviation.

CASAL2 does not allow an observation weight plus-group so the above defines all the calculations that are needed. A plus-group can be made by increasing the $W_{w_{max}}$ to a unlikely value.

Now the age-weight transition matrix, **TawO** is given by **Tal** % * % **Tlw**.

$$\mathbf{TawO}_{w,a} = \left(\sum_{l=L_{min}}^{L_{max}} \mathbf{Tlw}_{w,l,c} \mathbf{Tal}_{l,a,c} \right). \quad (3.6)$$

If growth and length-weight relationships are both not time-varying, then **TawO** should be saved and re-used for the other years. If both growth and length-weight parameters are not being estimated, and both are not time-varying, **TawO** only needs to be calculated once.

3.5. Predicted weight composition for single fish measurements

\vec{N}_c is the $n_{age} \times 1$ column vector of expected numbers-at-age based on $E[N_{a,c,m}]$ from above. Doing this isolates the transition matrix from selectivity in case it is time-varying.

First, we calculated the predicted weight composition for single fish measurements (i.e., the above derivation) by $\vec{W}_c = \mathbf{TawO}_c^T \vec{N}_c$. [$n_{weight} \times 1$ vector $n_{weight} \times n_{age}$ matrix times $n_{age} \times 1$ vector].

Element-wise, $\vec{W}_{c,w} = \sum_{a=A_{min}}^{A_{max}} \mathbf{TawO}_{w,a,c} \vec{N}_{c,a}$. Then normalize \vec{W}_c .

\vec{W}_c is put into the multinomial log-likelihood.

3.6. Accounting for data being mean weight composition

The above section does not account for data being means over n_i fish in each fish box, where i indexes length bins and since fish length in a particular fish box are similar, we can use the length bin boundary to approximate length. For the bluenose data, n_i can range from 2 to 18, with a median of 4. Using the length-weight relationship to predict its mean weight over several fish, we need to adjust the length-weight cv (say 10%) to reflects the variation of weight for several fish which are likely to be at similar lengths, i.e., we should use $cv_{weight} / \sqrt{n_i}$. If all boxes have 4 fish then we just use $10/2 = 5\%$ for the cv.

To accommodate this structure, the user needs to supply a vector with a n_i for each length bin, using the `length_bin_n` sub-command. This is not strictly correct, but it should be good enough. The re-weighting R code needs to be adjusted to take this structure (I think), which may provide further ways to adjusted the error structure.

The cv_l in $\sigma_{c,l} = cv_l \bar{W}_{c,l}$ above is a constant over both categories and lengths and so reflects the distribution of a single fish for the same number of fish in each fish box.

cv_l needs setting to $cv_{weight} \sqrt{n_l}$ at the start of each run since cv_{weight} is potentially estimable.

Recommendations

There might be the same issues as for lengths, except that we will not allow a weight plus-group. Should we try to mean weight and mean + 4 * standard deviation weight at the same ages as for lengths as a check that the weight bins are sufficient for the age plus group, but also ages 1 and 2, say, for the lower end (now mean - 4 * standard deviation weight)?

To ensure that the length bins (observation version) are adequate for the specified weight bins, CASAL2 will test both the first and last lengths (i.e., cap length in this case) to see how much of their weight distribution are within the weight bin range. A warning is printed if it is less than 95% since this means that potentially lengths outside the specified length bins make a contribution that should be included. The value of 95% is arbitrary. There is a report that outputs the percentage of the weight distribution covered for each length bin.

Specifying n_i in `length_bins_n` sub-command

An easy way to calculate the n_i s is to do a preliminary run using dummy n_i s and specifying a fishbox weight;

```
length_bins 10 13 14 16 17 #4 bins, last bin is from 16 to 17
length_bins_n 1* 4 # use 1s for all bins
fishbox_weight 20 # one fishbox is 20 kg
```

CASAL2 will calculate the n_i s for each category using its length-weight relationship, i.e., $20/(al^b)$, which for one category with $a = 0.0001$ and $b = 3$ comes to 200.0 , 91.0 , 72.9, and 48.8; these values are outputted automatically. These n_i s are inserted into the input file in place of the dummy n_i s and the `fish_box` sub-command commented out;

```
length_bins 10 13 14 16 17 #4 bins, last bin is from 16 to 17
length_bins_n 200.0 91.0 72.9 48.8 # replace 1s with calculated n
#fishbox_weight 20 # one fishbox is 20 kg
```

For more than one category, there will be results for each, i.e., a matrix of results, so the analyst must decide how to combine them, e.g., the median over categories, or the value from the most numerous category. Hopefully, the choice does not matter much so a few trial values should be tried in the development phase of the assessment.

[Use the mid-bin length?]

Length-based selectivity in an age-based model

The weight frequency code uses its own length bins which should cover all likely lengths. Using a length-based selectivity in an age-based model also has an age-length transition matrix with potentially a different set of length bins since it uses bins specified in `@model/length_bins`. There may be an inconsistency between them that may cause a bias, but it is hard to see how unless there is a mistake in the specification. The weight observation's length bins should enclose or equal that for the `@model/length_bins` sub-command used in the length selectivity. At the top end, the weight observation's length bins should go up to the largest length and so should cover the `@model/length_bins`. If `@model/length_bins` has a plus-group, then there will be a small part of the length range that is uncovered, but it will have very little biomass in it. The solution is to make the terminal length for the weight frequency data way above the largest length expected. If `@model/length_bins` specifies a plus-group, CASAL2 will print a warning.

Utility R functions

Need to check `extract` function from the fit output works for weight frequencies. Otherwise, need to write or adapt some code. We probably need some C++ report code.

3.7. Reports to use with this observation TO FIX LATER

```
@report <label>
type XXX #fits to observation
```

```
@report <label>
type XXX #check \% weight dist inside weight bins for each length bin
```

Need report code to output calculated `length_bins_n` which should be called automatically when `fishbox` sub-command is specified.

4. Proposed Input Format

Example input block.

```

5. Test Plan

Simulate some test data in R which can become a unit test.

Specify the model configuration and output to be used in `ProcessRemovalsByWeight.Test.cpp`

6. Text to be added to the User Manual

observations 7.7x

Process removals by weight

Removals by weight observations are observations of the relative number of individuals at weight, part way through a process of type `mortality_instantaneous`. This observation is exclusively associated

with the process of type `mortality_instantaneous`, and will produce an error if associated with any other process type.

The observation is supplied for a given year and time-step, for some selected age classes of the population (i.e., for a range of ages multiplied by a selectivity that is associated with the process).

The expectations from this observation are generated whilst the process is being executed. The expectation of numbers-at-age a for category c from exploitation method m ($E[N_{a,c,m}]$) are

$$E[N_{a,c,m}] = N_{a,c} U_{a,m} S_{a,c,m} 0.5 M_{a,c} \quad (6.1)$$

where $N_{a,c}$ are the numbers-at-age in category c before the process is executed, $U_{a,m}$ is the exploitation rate for age a from method m , $S_{a,c,m}$ is the selectivity, and M is the natural mortality.

The observation class accesses the variable $E[N_{a,c,m}]$ from the process and applies the age-length relationship specified in the model. This converts numbers-at-age to numbers-at-age and -length. In turn, numbers-at-length and -age are converted into numbers-at-age and -weight using the length-weight relationship and the spread of weights about a length, which are then converted to numbers-at-weight. The observations are aggregated by method and category depending on how the user specifies the observation, before converting numbers-at-weight to proportions and calculating the likelihood.

Similar to the proportions-at-length and removals-by-weight observation types, the user must supply a vector of weight bins. The observation-specific weight bins must be a sequential subset of the model weight bins, with no missing or added values. For example, if the model weight bins are 0 5 10 15 20 25 ... 100, then the observation-specific weight bins can be 20 25 30 35 40 45 50 but not 20 30 40 50. The length bins used in the intermediate step to get the numbers-at-age and -length uses the model length bins. For time-invariant growth and length-weight relationships, the transition matrix from numbers-at-age to numbers-at-weight is calculated once at the start of a run and stored to be reused in other years to speed up this observation class.

Currently, CASAL2 does not allow a weight plus group. WARNING: The user should check that the weight range for fish in the age plus-group is consistent with the specified weight bins for the years with weight compositional data (e.g., weight compositional data collected when the stock has been fished down and so the age plus-group has insignificant fish in it meets this criteria). Similarly for model length bins.

Likelihoods that are available for this observation are the multinomial and the lognormal. See Section ?? for information on the likelihoods.
